**Abstract.** We present colour-colour and colour-magnitude diagrams for RCW 57 (NGC 3576) based on L-band data at  $3.5\ \mu\text{m}$  taken with SPIREX (South Pole Infrared Explorer), and 2MASS JHK<sub>s</sub> data at  $1.25\text{-}2.2\ \mu\text{m}$ . A total of 251 sources were detected. More than 50% of the 209 sources included in the diagrams have an infrared excess. The IR-excess is interpreted as coming from circumstellar disks and hence gives the cluster disk fraction. Comparison with other JHK<sub>s</sub>L surveys, including results on 30 Doradus from a previous paper, support a very high initial disk fraction (>80%) even for massive stars, although there is an indication of a possible faster evolution of circumstellar disks around high mass stars. 33 sources only found in the L-band indicate the presence of heavily embedded, massive Class I protostars. We also report the detection of diffuse PAHs emission throughout the RCW 57 region.

**Key words.** Stars: circumstellar matter, formation, evolution, Hertzsprung-Russel (HR) and C-M diagrams, protoplanetary disks, pre-main sequence

## 1. Introduction

### 1.1. IR-excess as a measure of circumstellar disks

This paper is the second of two papers using IR-excess in the JHK<sub>s</sub>L plane (1.2 - 3.5  $\mu$ m) to measure the fraction of sources with circumstellar disks in high mass star forming regions. The first paper concerned 30 Doradus in the LMC (Maercker & Burton 2005, from now referred to as Paper I). IR-excess can be detected using near infrared colour-colour diagrams by comparing the position of sources relative to the reddening vectors due to interstellar extinction. The excess radiation above that of a blackbody can be explained by models of circumstellar disks around a young stellar object (eg. Lada & Adams 1992). Although this excess radiation can be detected using JHK<sub>s</sub> data (1.2 - 2.2  $\mu$ m) alone, the nature of IR-excess is not always clear. **On account of the difficulties of ground based observations at longer wavelengths, the L-band (3.5  $\mu$ m) proves to be the ideal wavelength for detecting circumstellar disks. JHK<sub>s</sub>L observations give a larger separation to the IR-excess sources in colour-colour diagrams, whereas JHK<sub>s</sub> observations tend to underestimate the fraction of stars with IR-excess.** Kenyon & Hartmann (1995) show the advantage of (K<sub>s</sub>-L) as a measure of IR-excess by comparing the frequency distributions in young stellar clusters for (H-K<sub>s</sub>) and (K<sub>s</sub>-L). Whereas the (H-K<sub>s</sub>) distribution has one clear peak at (H-K<sub>s</sub>)~0.2-0.4 and a long tail, the (K<sub>s</sub>-L) distribution has a clear second peak at (K<sub>s</sub>-L)~0.8-1.0 made up mostly of class II sources with optically thick, circumstellar disks.

### 1.2. RCW 57

This young massive star forming region, also known as NGC 3576, is one of the brightest HII regions in the infrared in our Galaxy. The kinematic distance is  $3.0 \pm 0.3$  kpc, adopted from De Pree et al. (1999). An asymmetrical structure in the region can be seen in the 21 cm map by Retallack & Goss (1980), which extends to the northeast but has a sharp cut off in the southwest. The spectral energy distributions of five objects detected using a 10  $\mu$ m map (Frogel & Persson 1974) suggest that these are protostellar objects with silicate absorption features, therefore indicating Class I objects (Persi et al. 1994). Near infrared photometry by Persi et al., together with an 8 - 13  $\mu$ m CVF spectrum of IRS 1 (IRAS 11097-6102 in the IRAS Point Source Catalogue), show that the majority of stars (> 70%) have an infrared excess in the JHK<sub>s</sub> plane. 19 of these sources could be matched with the present data, 15 of which we show can also be classified as having an infrared excess in the JHK<sub>s</sub>L plane. The sources discussed by Persi et al. are confined to the central region, confirming the youth of the cluster. Radio recombination lines were detected by McGee & Gardner (1968), Wilson et al. (1970) and De Pree et al. (1999). The detection of maser sources in CH<sub>3</sub>OH and H<sub>2</sub>O (Caswell et al. 1995 and 1989 respectively) are indications of early stages of star formation in a dense circumstellar environment. Thorough investigations of the central region have been undertaken by Figuerêdo et al. (2002) in the near-infrared (NIR), and Barbosa

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle3

et al. (2003) in the mid-infrared (MIR). Nine of the MIR sources match sources seen in the L-band image presented here. In the NIR, JHK<sub>s</sub> colour-colour and colour-magnitude diagrams show sources affected by excess emission, indicating the presence of circumstellar disks around the less massive members of the cluster (Figuerêdo et al. 2002). Eight spectra of the brightest sources show rising continua towards the IR. Three of these have a clear infrared excess. The detection of CO bandheads ( $2.2935\mu\text{m}$ ) in emission and absorption indicates the presence of several sources still heavily embedded in their stellar birthclouds (Figuerêdo et al. 2002, Barbosa et al. 2003). Based on the radio data (Goss & Shaver 1970), RCW 57 can be classified as a Giant HII (GHII) region, with  $1.6 \times 10^{50}$  photons  $\text{s}^{-1}$  in the UV (defining sources brighter than  $10^{50}$  Lyman continuum photons per second as GHII regions (Figuerêdo et al. 2002)). A possible ionizing source has been found at the peak emission of the 3.4 cm map (DePree et al. 1999), the source being a cluster of stars that have broken out of their natal cocoons but remain hidden behind dark clouds along the line of sight (Barbosa et al. 2003). The radio peak emission (at  $\sim$  RA 11h11m51s, Dec  $-61^\circ 18' 45''$  (J2000)) is also hidden behind clouds in the SPIREX image. This is further confirmed by Walsh et al (2001), who find the peak of the 8.64 GHz continuum emission to lie at approximately the same position, behind clouds in the N-band image (their Fig. 2). In their follow up survey, Barbosa et al. for the first time resolved IRS 1 into four sources in the  $10\mu\text{m}$  band, approximately  $1.5''$  apart from each other (Nos. 48, 50, 60 and 60b in their paper. Source numbers labelled in Table 7 with 'No' and a number are from Barbosa et al.). One of these shows evidence for a UC HII region and they conclude that the sources in the central region of RCW 57 are in the UC HII region phase. The position of IRS 1 coincides with the brightest L-band source in our study ( $m_L=4.1$ , #88, Table 7) and is also found in the L-band by Moneti (1992) with magnitude  $m_L=4.05$ . Barbosa et al. also found a new MIR source, without a counterpart in the NIR, which is possibly a hot core. In the central region a strong CO  $J = 2 - 1$  line at 230 GHz was observed by White and Phillips (1983). Shock-excited H<sub>2</sub> line emission may also indicate the presence of gas outflows (Figuerêdo et al. 2002).

## 2. Observations

### 2.1. L-band data from SPIREX

The data at  $3.5\mu\text{m}$  was taken with the 60 cm South Pole InfraRed Explorer (SPIREX) (Hereld 1994; Burton et al. 2000) at the Amundsen-Scott South-Pole Station using the Abu camera equipped with a  $1024 \times 1024$  InSb array (Fowler et al. 1998) in July and August 1999. Observations were carried out using the L-band filter ( $\lambda_{\text{central}}=3.514\mu\text{m}$ ,  $\Delta\lambda=0.618\mu\text{m}$ ) and had a field of view of  $10'$  and pixel scale  $0.6''$ . The image is a mosaic of a series of 3 minute frames, each shifted by  $15''$  from each other, interleaved with separate sky observations, and comprises a total of 60 minutes of on-source integration. Reductions were done automatically

4Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle using the SPIREX/Abu pipeline<sup>1</sup>. Unfortunately the data was not flux calibrated and separate observations were necessary to determine the calibration, as discussed in Paper I (see § 2.4).

## 2.2. Narrow Band Filters from SPIREX

In addition to the L-band data, images were obtained through three narrow band filters, centred on the wavelengths of the H<sub>2</sub> v=1-0 Q-branch lines, a PAHs emission feature, and the hydrogen Br  $\alpha$  line. The line centres of the filters were 2.42, 3.30 and 4.05  $\mu\text{m}$ , respectively, and their widths 0.034, 0.074 and 0.054  $\mu\text{m}$ . For the H<sub>2</sub> and PAHs filters the data were self-calibrated using interpolated values for magnitudes of the sources IRS1, Persi 43 and Persi 106 (stars 88, 74 and 124, respectively in Table 7) from those we determined in this Table for the K<sub>s</sub> and L bands. For the Br  $\alpha$  filter, we self-calibrated based on a flux for IRS1 of 16 Jy at 4 $\mu\text{m}$ , as measured by McGregor et al. (1984).

## 2.3. JHK<sub>s</sub>-band data from 2MASS

The L-band observations were complemented with JHK<sub>s</sub> data from the 2MASS point source catalogue (PSC) (Cutri et al. 2003) and atlas images<sup>2</sup>. The 2MASS telescopes (Kleinmann et al. 1994) scanned the sky in both hemispheres in three near infrared filters (J, H and K<sub>s</sub>; 1.25, 1.65 and 2.2  $\mu\text{m}$  respectively) with limiting magnitudes of  $m_J=15.8$ ,  $m_H=15.1$  and  $m_K=14.3$ . The L-band data was first matched with sources in the PSC. Photometry was also performed on the K<sub>s</sub>-band atlas images to derive the magnitudes for any sources that could not be matched with those in the PSC.

## 2.4. Calibration data from CASPIR

Since the SPIREX L-band image was not flux calibrated, additional observations were carried out using the Australian National University (ANU) 2.3 m telescope at Siding Spring Observatory, equipped with CASPIR (Cryogenic Array Spectrometer/Imager)(McGregor 1994). The observations were carried out in early April 2004 together with the calibration observations for 30 Doradus (Paper I). A narrow band filter ( $\lambda_{\text{central}} = 3.592 \mu\text{m}$ ,  $\Delta\lambda = 0.078 \mu\text{m}$ ) was used to avoid saturation due to sky brightness, in contrast to the broader band it was possible to use with SPIREX because of the lower sky background at the South Pole. The standard star used to calibrate the images is listed in Table 1 and the stars in the SPIREX image used to determine the zero-point correction are listed in Table 2. The individual error for the calibrated stars is  $\sim 0.05$  mags which leads to a weighted error in the zero-point correction of  $\sim 0.03$  mags and is included in all subsequent error calculations.

### 3. Results

#### 3.1. Photometry

The L-band image of RCW 57 from SPIREX is shown in Figure 1 and an enlargement of the central region overlaid with contour lines showing the nebulosity is shown in Figure 2. The same steps to obtaining the photometry were undertaken as described for 30 Doradus in Paper I, including fitting coordinates using the *Karma* package<sup>3</sup>, running *IRAF/daophot* to get the photometry and adding 400 artificial stars using *addstar* to estimate the errors. This last step resulted in a 90% completeness limit of 11.2 mag in the L-band. **The individual errors for the L-band magnitudes were given by *IRAF/daophot*.** Matching sources not in the 2MASS PSC catalogue

<sup>3</sup> <http://www.atnf.csiro.au/karma/>

**Fig. 2.** Enlargement of the central region of RCW 57 at L-band ( $3.5 \mu\text{m}$ ) with contours showing the nebula. Contour levels are 0.03, 0.2, 0.4, 0.7, 1.0, 1.7, 2.3, 3.0, 8.3 and  $20 \text{ mJy/arcsec}^2$ .

**Fig. 3.**  $\text{HK}_s\text{L}$  (Blue=H, Green= $\text{K}_s$ , Red=L) composite colour image of RCW 57 created using 2MASS and SPIREX images. Regions bright in the L-band ( $3.5 \mu\text{m}$ ) can be seen in red or orange, indicating the presence of young stellar objects. Prominent dust lanes are also apparent.

with photometry performed on the 2MASS  $\text{K}_s$ -band atlas images resulted in an additional 17 matches.

The mosaiced SPIREX image suffered from irregular distortions (in the upper most left part of the image a recognizable patterns of 3 stars was  $8''$  off). These were however small over the largest part of the image, and the L-band data could carefully be matched with the PSC and  $\text{K}_s$ -band images by marking the sources in the images and then selecting matches ‘by hand’, taking local distortions into account. Table 3 lists the statistics for detections in the various bands including the statistics when applying the 90% completeness limit.

**Fig. 4.** Contour map of the emission measured through the H<sub>2</sub> Q-branch 2.42 μm narrow band filter, overlaid on the 2MASS image of the K<sub>s</sub> band emission from the central of RCW 57. Contours levels are at 0.8, 1.5, 2.2, 2.9, 4.3, 7.2 and  $13 \times 10^{-4}$  Jy arcsec<sup>-2</sup>.

**Fig. 5.** Contour map of the emission measured through the PAHs 3.3 μm narrow band filter, overlaid on the L-band image of RCW 57. Contours levels are at 2.2, 3.9, 5.7, 10 and  $19 \times 10^{-3}$  Jy arcsec<sup>-2</sup> for continuum, or equivalently  $4.4, 8.0, 12, 20$  and  $38 \times 10^{-17}$  W m<sup>-2</sup> arcsec<sup>-2</sup> if it is line emission.

### 3.2. Sensitivity

The detection threshold was taken to be three times the standard deviation  $\sigma_{sky}$  of a typical region of sky near each source. This resulted in a limit of  $\sim 12$  mag at L-band, corresponding to the 84% completeness limit. The faintest source detected has a magnitude of  $m_L = 13.5$  (69% completeness limit). However, only sources above the 90% completeness limit at  $m_L = 11.2$  mag are included in the determination of the IR-excess fraction (§ 4.2).

**Fig. 6.** Contour maps of the emission measured through the Br  $\alpha$  4.05  $\mu$ m narrow band filter, overlaid on the L band image of the central region of RCW 57. Contour levels are at 3.2, 4.9, 6.5, 9.8, 16, 23 and  $61 \times 10^{-2}$  Jy arcsec $^{-2}$ .

### 3.3. Foreground contamination

Unfortunately off-source comparison images were not available for the SPIREX data. We therefore estimated the contamination by foreground stars using the (J-K<sub>s</sub>) colours of the stars, to determine a limiting (J-K<sub>s</sub>) colour due to interstellar reddening. Assuming that sources that are part of RCW 57 are additionally reddened, excluding all sources bluer than the (J-K<sub>s</sub>) limit gives a first order estimation of the number of foreground stars. Figuerêdo et al. (2002) use the star HD 97499 to determine the interstellar component of the reddening to RCW 57. This results in an extinction parameter of  $A_K=0.43$  which in turn gives a limiting (J-K<sub>s</sub>) colour of 0.7. This limit corresponds also to a gap in the J vs (J-K<sub>s</sub>) diagram for RCW 57, indicating main sequence stars between the source and Earth on the blue side of the gap and the stars belonging to RCW 57 or further away on the right side of the 0.7 (J-K<sub>s</sub>) colour limit. Applying this limit to the sources detected in RCW57 results in 17 potential foreground stars. Of these, 3 have moderate IR-excess ((K<sub>s</sub>-L)<2) and 7 have larger excess ((K<sub>s</sub>-L)~3-5). The extreme red colours in potential foreground stars is suprising. However, a closer inspection of the K<sub>s</sub>- and L-band images shows that the 2MASS sources possibly are foreground objects close to the position of embedded stars (**on the sky**), and therefore result in large (K<sub>s</sub>-L) colours. In two cases (# 33 and #43), the J-band magnitude is only the 95% upper confidence limit (the uncertainty in the magnitude is given as ‘null’ in the PSC, indicating that the source either was not detected in J-band or is inconsistently deblended), resulting in an uncertain (J-K<sub>s</sub>) colour. Excluding these potential foreground stars decreases the disk fraction from 55% to 54% (see § 5.3). Likely foreground stars are indicated in Table 7 and are marked with boxes in Figs. 7 to 9.

### 3.4. Narrow Band Filters

The three narrow band images are shown in Figs. 4, 5 and 6. In all three images the contours showing the emission through the line filters are similar to the nearby continuum images they are overlaid on. Indeed, there is no clear evidence for line emission in either the H<sub>2</sub> or Br  $\alpha$  images, although this does not preclude their presence.

Oliva & Moorwood (1986) report a detection of  $2.6 \times 10^{-13}$  erg cm<sup>-2</sup> s<sup>-1</sup> through a 30'' beam centred on RCW 57 for the H<sub>2</sub> Q-branch emission, with the flux falling to approximately one tenth that value a beam away. Their measurements were through a CVF of similar spectral resolution to the narrow band filter we employed, with the line being approximately 10% of the continuum. This would not be apparent in our image without careful continuum subtraction from the narrow band image. While H<sub>2</sub> emission is indeed likely present in RCW 57, all we can conclude is that it is not distinguishable from the continuum in a narrow band filter image. There are no extended regions of bright pure H<sub>2</sub> line emission evident.

Similarly, we cannot distinguish any Br  $\alpha$  emission from the continuum at 4 $\mu$ m in a narrow band filter, although again this line is most likely present. Moorwood & Salinari (1983) report a detection of Br  $\alpha$  10''S of IRS1, but at a level that is about 10% of the continuum level we measure. They also report a detection of Br  $\alpha$  on IRS1 itself, though at a level inconsistent with an upper limit of McGregor et al. (1984). In either case, the level would not be distinguishable from the strong continuum from IRS1 in a narrow band filter.

We can, however, report a clear detection of PAHs emission from RCW 57. While the diffuse emission in the PAHs and L band images are similar in morphology, with extended emission around IRS1 and a filament extending from it to the NE, the contrast of the diffuse emission to the stellar sources is clearer through the PAHs filter than through the L band filter. A quantitative comparison suggests that typically about one third of the diffuse flux measured in the L band filter must come from the PAHs feature at 3.3 $\mu$ m. It is likely that scattered continuum dominates the remaining diffuse emission at L band, although we cannot demonstrate that from the data here. The PAHs emission is presumably fluorescently excited by the far-UV photons also generated by the ionizing source(s) which excites the HII region. As can be seen in our Figure 5, typical fluxes for the 3.3 $\mu$ m PAHs emission are around  $10^{-16}$  W m<sup>-2</sup> arcsec<sup>-2</sup> in the nebulosity.

## 4. Analysis

### 4.1. Colour-colour and colour-magnitude diagrams

Figs. 7 to 9 show the colour-colour and colour-magnitude diagrams. Fig. 7 shows the (J-H) colour vs. (K<sub>s</sub>-L) colour, Fig. 8 the (J-H) vs. (H-K<sub>s</sub>) colours and Fig. 9 the L-band magnitude vs. (K<sub>s</sub>-L) colour. The diagrams were created using the JHK<sub>s</sub> data from 2MASS and the L-band data from the SPIREX image. Only sources above the 90% completeness limit were included. The main sequence (thick solid line) for spectral types O6-8 to M5 and the giant branch (thin solid line) for spectral types K0 to M5 are plotted in each diagram. The sequences were plotted using their

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

**Table 3.** Number of detections in the different bands. The first column gives the total number of detections in the SPIREX image. The second column gives the number of stars that could be matched with the 2MASS PSC. Column three lists the number of stars additionally matched by comparison of the  $K_s$ - and L-band images. The last column lists the number of stars only found in the SPIREX L-band image. The second row lists the respective numbers for stars brighter than the 90% completeness limit. Using the  $(J-K_s)$  colour limit determined in § 3.3 suggests 17 of the stars detected at JHK<sub>s</sub>L are likely foreground stars.

	Total	JHK <sub>s</sub> L	K <sub>s</sub> L	L
all stars	251	201	17	33
$m_L < 11.2$ (90% limit)	209	168	8	33

intrinsic colours (Koorneef 1983) and their absolute visual magnitudes (Allen 1973). Reddening vectors up to an extinction of  $A_V=30$  mags are plotted as dashed lines, assuming an extinction law  $\propto \lambda^{-1.7}$ . The distance modulus used was 12.4 magnitudes, corresponding to the distance of 3 kpc to RCW 57. **The crosses in the lower right corners indicate the mean errors for the stars in each figure.**

#### 4.2. Fraction of reddened sources

The fraction of reddened sources was determined taking the individual errors for each star into account. Stars which lie at least  $1\sigma$  error to the right and below the reddening band are counted as having an IR-excess and are marked with the star symbol. IR-excess stars in the JHK<sub>s</sub>L plane are marked with the same symbol in Figs. 8 and 9 as well. In Figure 9, stars that are additionally only detected in  $K_s$  and L (diamond shaped symbols) are included. Stars only detected in the L-band can be included by providing a lower limit for the  $(K_s-L)$  colour using the 2MASS sensitivity limit at  $K_s$  (14.3 mag). These are indicated as circles and lie to the right of their positions in the colour-magnitude diagram. By comparing the location of the stars in Fig. 9 to the location of already identified IR-excess sources (star shaped symbols), it is possible to also estimate which of the stars seen only at  $K_s$  and L also have an IR-excess. Of the 8 stars that lie above the 90% completeness limit, 6 occupy this region and so are counted as having an IR-excess. The 33 stars only detected in the L-band also lie in the region occupied by the IR-excess stars and therefore all of these are counted as having an IR-excess. The statistics are listed in Table 4. The uncertainty in the number of stars with IR-excess is determined by counting the number of IR-excess sources when assuming a  $2\sigma$  distance to the reddening band. The variation in this number gives an estimate of the uncertainty in IR-excess sources. This procedure excludes four sources from the JHK<sub>s</sub>L data set. The sources only detected at  $K_s$  and L, and only at L, are not affected by this consideration. Thus, the determined fraction of IR-excess sources is  $55\pm2\%$ . The JHK<sub>s</sub> data alone (Fig. 8), would yield only 25 IR-excess sources, compared to 75 excess sources in the JHK<sub>s</sub>L diagram. This would lead to a considerable underestimation of the CDF. Our JHK<sub>s</sub> diagram looks similar to the one presented by Figuerêdo et al. (2002) (their Fig. 4). The majority

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

of sources lie along the reddening vector, with several sources displaying clear IR-excess at  $(H-K_s) > 1.5$ . Previous determinations of the fraction of sources with IR-excess in JHK<sub>s</sub> colour-colour diagrams (Persi et al. 1994), show that >70% of the sources have significant IR-excess. This is much higher than the fraction of excess sources determined here. However, the region covered in Persi et al. is only 340×340 square arc seconds, compared to a radius of ~440 arc seconds for the region covered in this paper. If an area equal to the region in Persi et al. (~3' in radius) is considered, the fraction of IR-excess sources increases to  $79 \pm 2\%$  (Table 5 and § 5.3). The determination of sources not part of RCW 57 is only a first order estimate (§ 3.3). In particular, the estimate is a lower limit on the CDF since it may not exclude all potential background stars. Contamination from background stars is likely to be more significant in the outer regions of the image where these are not hidden behind the molecular cloud, so resulting in a lower CDF.

#### 4.3. Luminosity Function

Figs. 10 and 11 show the luminosity function for all sources in RCW 57, and IR-excess sources, respectively. Vertical lines indicate the 90% completeness limit. Both diagrams cover the range from  $m_L = 7.5$ -13.5 and peak at  $m_L \sim 10$ . The distribution is somewhat higher and narrower when only taking IR-excess sources into account (Fig. 11). Comparing the L-band luminosity function with the L-band magnitudes of main sequence stars, the diagrams cover the range from spectral types A3 to O5 and peak at early type B stars. Using the spectral types, it is possible to make crude estimates of the stellar masses. For early type B stars the masses lie at approximately 7-17  $M_\odot$  (Allen 1973). Both diagrams span a mass range of ~2-60  $M_\odot$ , confirming that RCW 57 is a high mass star forming region. However, the IR-excess might severely bias the determination of spectral types towards earlier type stars and higher masses, and so the results here can only be taken as indicative. There is a possible turnover at the 90% confidence limit in the L-band luminosity function (Fig. 10). A turnover is however not seen in the K<sub>s</sub>-band luminosity function (KLF) (Figueroa et al. 2002) and an IMF derived from the KLF gives a slope of  $\Gamma = -1.62$ , which is consistent with the Salpeter value (Salpeter 1955). The KLF derived in Figueroa et al. included correction for non-cluster members, interstellar reddening, excess emission and photometric completeness. The resulting cluster mass integrated from their derived IMF, is  $M_{cluster} = 5.4 \times 10^3 M_\odot$  (Figueroa et al. 2002). This is an upper limit, as their IMF is likely to be overestimated due to excess emission. The IMF derived from the L-band luminosity function in Fig. 10 has a slope of  $\Gamma = -1.42$ . The integrated cluster mass for stars above the 90% completeness limit is  $\sim 10^4 M_\odot$  (using  $M_{lower} = 5.8 M_\odot$  and  $M_{upper} = 100 M_\odot$ ). However, the cluster mass is dominated by contribution from stars below the completeness limit, and so is highly sensitive to the derived value for the slope of the IMF.

**Fig. 7.** JHK<sub>s</sub>L colour-colour diagram for RCW 57. The thick solid line shows the position of the unreddened main sequence for spectral types O6-8 to M5. The thin solid line above shows the giant branch for spectral types K0 to M5 and extends from (J-H)=0.5, (K<sub>s</sub>-L)=0.07 to (J-H)=0.9 to (K<sub>s</sub>-L)=0.19. The dashed lines show the reddening vector up to  $A_V = 30$  assuming an extinction law  $\propto \lambda^{-1.7}$ . Star shaped symbols are stars identified as having an IR-excess (§ 4.2). Sources in squares are have (J-K<sub>s</sub>)<0.7 (see § 3.3). The cross in the lower right of the diagram indicates the mean errors for all stars. 209 stars lie above the 90% completeness limit and 75 of these lie outside the reddening band and are therefore considered to have IR-excess (Table 3 and 4).

**Fig. 8.** JHK<sub>s</sub> colour-colour diagram for RCW 57. The same symbols as in Figure 7 are used. The giant branch extends from (H-K<sub>s</sub>)=0.13 to 0.31 with the same values for (J-H) as in the previous figure. **The cross in the lower right corner indicates the mean error for all stars.** The diagram shows the same sources as in the JHK<sub>s</sub>L diagram using only the JHK<sub>s</sub>-band data. Here the stars are clearly less separated than sources with IR-excess compared to using the L-band data. In this diagram only 25 sources would be classified as having IR-excess, compared to 75 in Figure 7, leading to an underestimate of the cluster disk fraction.

**Fig. 9.** Infrared  $L$  vs  $(K_s-L)$  colour-magnitude diagram for RCW 57. The thick solid line shows the main sequence for spectral types B5 and earlier, the thin solid line the giant branch for the same spectral types as in the other diagrams. The dashed line shows the reddening vector up to  $A_V=30$ . Star shaped symbols are the same IR-excess sources as in Figure 7. Diamond shaped symbols are stars only detected in  $K_s$ - and  $L$ -band and circles show the lower  $(K_s-L)$  limit for stars only detected in  $L$ -band (§ 4.2). Squares indicate possible foreground stars with  $(J-K_s)<0.7$ ; § 3.3. **The cross in the lower right corner indicates the mean error for all stars.** 6 of the 8 stars detected in  $K_s$  and  $L$  occupy the same region as the stars with IR-excess from Figure 7. All 33 stars detected only in  $L$ -band are also in the region. These stars are also classified as IR-excess sources and are counted towards the total disk fraction (Table 4).

**Fig. 10.**  $L$  band luminosity function of all stars detected at  $L$ -band in the SPIREX image of RCW 57. Stars are detected down to  $m_L \sim 13.5$ , corresponding to unreddened A5 stars at the distance of RCW 57. The upper limit is  $m_L \sim 4$ . O5 type and earlier stars correspond to an  $L$ -band magnitude  $m_L \sim 7.5$ . The distribution peaks at  $m_L \sim 10$  indicating early type B stars. Based on the spectral types the mass range is from 2-60  $M_\odot$  and peaks at 7-17  $M_\odot$ . The vertical line shows the 90% completeness limit.

**Table 4.** Number of stars found with IR-excess and the reddening fraction. Numbers in the JHK<sub>s</sub>L, K<sub>s</sub>L and L columns are the number of stars with IR-excess found in the respective bands. These are listed assuming 1 $\sigma$  and 2 $\sigma$  distances from the reddening band. Column 5 gives the total number of sources with IR-excess at 1 $\sigma$  and 2 $\sigma$ . Column 6 gives the cluster disk fraction. Excluding possible foreground stars decreases the CDF to  $\sim 54\%$ . Only sources that are brighter than the 90% completeness limit (11.2 mag in L-band) are including in calculating the fraction of IR-excess sources.

distance	JHK <sub>s</sub> L	K <sub>s</sub> L	L	total	frac
1 $\sigma$	75	6	33	114	$55 \pm 0.5$
2 $\sigma$	71	6	33	110	$53 \pm 0.5$

**Fig. 11.** The percentage of all sources with an IR-excess within each magnitude interval. The width of the distribution is narrower than in Figure 10, but covers the same range of spectral types and masses. The vertical line shows the 90% completeness limit.

## 5. Discussion

### 5.1. IR-excess as an indicator of circumstellar disks

The location of stars in the JHK<sub>s</sub>L diagram (Fig. 7) shows that  $55 \pm 2\%$  of the sources lie outside of the reddening vector defined by interstellar extinction. These sources have an IR-excess, displaying more emission than simply a reddened stellar photosphere. As discussed in §1, the position of these stars in the colour-colour diagram can be explained by models of circumstellar disks around classical T Tauri stars and AeBe stars, depending on the characteristics of the disk (e.g. whether these have central holes, varying inclination angles etc) (Lada & Adams 1992). The IR-excess stars here are therefore interpreted as stars with circumstellar disks, with the fraction of IR-excess stars taken to be equal to the cluster disk fraction (CDF). The presence of disks is also supported by the presence of the CO 2.3  $\mu\text{m}$  bandhead emission or absorption, found in four objects in RCW 57 (Figuêdo et al. 2002). The preferred model for such molecular emission is that it arises from the inner portions of disks (Barbosa et al. 2003). Such an identification has

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

**Table 5.** Cluster Disk Fraction as a function of angular distance from the centre of RCW 57 (central coordinates are RA 11h11m53.41s, Dec -61°18'22.5'') based on the fraction of stars with an IR excess within each radius.

radius	CDF
(arcmin)	%
<1	95±1
<2	90±1

<5	66±1
<6	62±2
<7	58±2
>7	55±2

been made, for example, for CO bandhead emission seen in the massive star formation region of M17, where optical spectra of some of the stars also indicate the presence of circumstellar disks (Hanson et al. 1997; Barbosa et al. 2003).

### 5.2. Spatial Distribution of IR-excess sources

The spatial distribution of IR-excess stars can be seen in Figure 12. Squares represent sources detected in all four bands, plus signs sources only found in K<sub>s</sub>-and L-band and crosses indicate the positions of sources only found in L-band. Sources with IR-excess are mainly located in the central cluster and follow the nebulous arcs outside the cluster. Stars found in all four bands dominate the cluster, while stars only found in L-band predominantly lie in the nebulous arcs away from the centre. However, four of the six reddest stars lie in the central cluster (labelled #220, #227, #229 and #230 in Fig. 12) (§ 5.4). Table 5 shows how the CDF varies at increasing radii from the centre, and Table 6 shows how the CDF and surface density of all detected stars and IR-excess stars varies in regions at increasing distances from the centre. There is a slight increase in disk fraction and density at a distance of 3'–4' which coincides with the nebulous arcs to the northeast and east of the central cluster. Figuerêdo et al. (2002) find a gradient in the spatial distribution of **near IR (H-K)** colour indices towards the southwest. They suggest that this indicates a progression of star formation from the northeast to the southwest. Fig. 12 however shows IR-excess sources throughout the source, favoring star formation without any particular preferred gradient.

### 5.3. The Cluster Disk Fraction

The cluster disk fraction determined here, based on the colour-colour and colour-magnitude diagrams (Figs. 7 to 9) for the entire region of the image, is ~54% when excluding potential fore-

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

**Table 6.** Variation of the cluster disk fraction and the surface density of sources in annuli at increasing angular distance from the centre (same central coordinates as in Table 5). The disk fraction decreases with increasing angular distance, though rises slightly however at a distance of 3-4 arcmin. The surface density of all stars and IR-excess stars behaves similarly. The slight increase coincides with the nebulous arcs to the northeast and east of the cluster seen in Figure 12, where many of the sources only detected in L-band lie. Errors in the values for the surface density are  $\pm 0.1$  sources per arcmin<sup>2</sup>.

distance (arcmin)	fraction %	no. stars (per arcmin <sup>2</sup> )	no. IR-excess sources (per arcmin <sup>2</sup> )
0-1	$95 \pm 1$	7	6.7
1-2	$82 \pm 1$	1.8	1.5
2-3	$59 \pm 5$	1.4	0.8
3-4	$64 \pm 3$	1.6	1.0
4-5	$50 \pm 2$	1.6	0.8
5-6	$45 \pm 7$	0.8	0.4
6-7	$27 \pm 5$	0.5	0.1

**Fig. 12.** Spatial distribution of IR-excess sources in RCW 57. Squares mark stars with an IR-excess found in the JHK<sub>s</sub>L-bands, plus signs mark stars with an IR-excess found only in the K<sub>s</sub>L-bands and crosses mark stars with an IR-excess only found in L-band (there is no difference between white/black symbols, with the colour chosen in the nebulous regions for clarity). The stars with labels are the six reddest sources with  $(K_s-L) > 5$  and are only seen in L-band.

ground stars (Table 4). However, as discussed earlier this is probably a lower limit due to the contamination of background sources in the outer regions of the image. The CDF together with the ages of the cluster, the CDF can give information about the evolution and lifetime of circumstellar disks. In particular, since RCW 57 is a region of massive star formation (see § 1.2 and § 4.3), it is possible to gain valuable information about the formation of massive stars and their circumstellar disks. Unfortunately, the age of RCW 57 is not well known. However, there are several indicators for recent and ongoing star formation, such as CO 2.3  $\mu$ m bandhead emission and absorption, the detection of CH<sub>3</sub>OH and H<sub>2</sub>O maser sources and the clustering of IR-excess

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

sources in the central region (§ 1.2 and § 5.2). Within a radius of  $\sim 4'$  of the centre of the cluster, the fraction of sources with an IR-excess is  $\sim 73\%$  (Table 5). This high IR-excess fraction, interpreted as the cluster disk fraction (CDF) (§ 5.1), suggests that the region is young. These signs of early stages of star formation, combined with the fast evolution timescales for massive pre-main sequence stars (on the order of  $10^5$  to  $10^6$  years), indicates an upper limit for the age of RCW 57 of  $\sim 1$ -2 Myr, and an age spread within this limit.

In Fig. 13, the resulting CDF and age of RCW 57 are compared to earlier JHKL surveys of clusters in the Galaxy (Haisch et al. 2001) and the results for 30 Doradus from Paper I. For the purpose of comparison we have assumed an age for RCW 57 of  $1.5 \pm 1$  Myrs. The data from Haisch et al. was determined in a similar way to this paper using JHKL colour-colour diagrams. The ages for the Trapezium, IC 348, NGC 2264 and NGC 2024 were determined using pre-main-sequence (PMS) tracks, the ages for NGC 2362 and NGC 1960 were determined using post-main-sequence isochrone fitting in HR-diagrams (Haisch et al. 2001). The systematic error in the upper right corner of Fig. 13 gives their estimate of the overall systematic error introduced in using different PMS tracks. The clusters included cover a range of masses and ages (0.3 Myr to 30 Myr). The error in the CDF for RCW 57 is  $\pm 12\%$  and includes the error due to the uncertainty in the number of IR-excess sources ( $\pm 2\%$ ). It also allows for the uncertainty in determining the number of foreground stars. The position of RCW 57 in Fig. 13 lies below the least-squares straight line fit to the data of Haisch et al.. However, this position on the diagram is clearly uncertain. The CDF determined includes data covering the entire SPIREX image, although the outer regions might be biased towards stars not belonging to RCW 57. If we only take the inner  $5'$ - $6'$  into account (cf. the region considered by Persi et al. 1994), this increases the CDF to 60-65%. In the central arcmin the disk fraction is even higher,  $\sim 95\%$ . Considering the additional uncertainty in the age, our data is consistent with the predictions of Haisch et al. for the relation between disk fraction and age. Certainly, the disk fraction is much higher than that determined for the oldest cluster NGC 2362. However, as with 30 Doradus (Paper I), our best estimates of the disk fraction as a function of age lie below the relation determined by Haisch et al. Both 30 Doradus and RCW 57 are high mass star formation regions, where the evolution timescales for the most massive members is expected to be less than  $10^6$  yrs. Nevertheless, if the CDF had been determined from the JHK<sub>s</sub> data alone, the result would have appeared to fall significantly below that of the Haisch et al. data. In RCW 57, it is possible that the external photoevaporation of circumstellar disks decreases the CDF. Lifetimes for photoevaporated disks may then be of order of 0.1 Myr (cf. Hollenbach et al. 1994). If this is true for RCW 57, the initial disk fraction would be higher than determined here from the JHK<sub>s</sub>L data. Extrapolating the best fit suggests that the age for circumstellar disks is no more than  $\sim 6$  Myr.

**Fig. 13.** Cluster disk fraction (CDF) for 7 clusters by Haisch et al. (2001) and 30 Doradus (Paper I) vs their mean ages. The CDFs were determined using JHK<sub>s</sub>L data as described in the text (§ 5.3) and Paper I. The location of RCW 57 is indicated by a circle with error bars indicating the uncertainty in age and disk fraction. The dot-dashed line is the best fit determined by Haisch et al. (2001).

#### 5.4. The Cluster Core

Several very red sources ( $(K_s-L) > 4.5$ ) lie in the central region ( $r < 1'$ ) and in the bright arc to the southeast of the central cluster (Fig. 12). The six reddest sources ( $(K_s-L) > 5$ ) in our data were only detected in the L-band, with their colours therefore only being lower limits. These are labelled in Fig. 12. Four of these lie in the central cluster close to the position of IRS 1 (#220, #227, #229 and #230). The remaining two lie in the bright arc to the southeast (#232 and #235). While we cannot classify these sources based on a single measurement, Barbosa et al. (2003) examined the cluster core in the mid-IR, determining spectral indices for 3 sources. Comparing these to indices for low mass protostars, they find two (Nos. 48, 50) that would be classified as Class I objects (two of the four sources in IRS 1 that were resolved by Barbosa et al., see § 1.2). Silicate absorption features in the spectra of the five objects seen at  $10\mu\text{m}$  by Frogel & Persson (1974) in the inner 1.4 square arc minutes, also indicates Class I protostellar objects. Barbosa et al. (2003) overlay a K-band image of the cluster core with the radio continuum map by DePree et al. (1999). None of their sources can be associated with the radio peak emission and they suggest that the ionizing source lies hidden behind dark clouds in the line of sight. The position of the radio peak emission is confirmed by Walsh et al. (2001). As with the results from Barbosa et al., none of our L-band sources can be connected with the radio continuum peak, which coincides with the dark lane just south of the bright cluster core (RA 11h11m51s, Dec  $-61^\circ 18' 45''$  (J2000)). The sources we see only at L-band are likely to be massive Class I protostars with circumstellar disks, still heavily embedded in their dust shells (Lada et al. 2000). The fact that they are not

Please give a shorter version with: \authorrunning and/or \titilerunning prior to \maketitle

detected at shorter wavelengths, and occupy the same region in the colour-magnitude diagram as the IR-excess stars, gives further support to this suggestion. In addition, 22 sources only seen in the L-band are found in the nebulous arcs further away from the cluster core (see Fig. 12). This indicates the possible presence of massive protostars in these regions as well, suggesting that massive star formation is not just confined to the central cluster.

## 6. Conclusions

As the second of two papers on IR-excess in massive star forming regions measured by the SPIREX telescope at the South Pole, L-band photometry for the giant HII region RCW 57 has been presented. The L-band photometry from SPIREX was combined with JHK<sub>s</sub> data from 2MASS to determine the fraction of sources with IR-excess in JHK<sub>s</sub>L colour-colour and colour magnitude diagrams. As for 30 Doradus, it is apparent that the JHK<sub>s</sub> data alone would considerably underestimate the fraction of IR-excess sources, with only 25 sources classified as having an IR-excess. Using the JHK<sub>s</sub>L data, 75 are counted towards the total fraction of stars with an IR-excess in the JHK<sub>s</sub>L diagram. More than 50% of detected L-band sources have an IR-excess. This is, however, likely to still be a lower estimate, since foreground contamination has not fully been taken into account. Limiting the analysis to the inner  $\sim 6'$  of the source, the disk fraction increases to  $\sim 65\%$ . The results were compared to earlier surveys (Haisch et al. 2001) of clusters of varying ages and masses in the Galaxy (**ages between 0.3 Myr for NGC 2024 to 4.5 Myr for NGC 2362; masses down to 0.13 M<sub>⊙</sub> for NGC 2024**). Although the CDF for RCW 57 lies at the lower end of what is predicted by Haisch et al., it is still consistent with their data, confirming a very high initial disk fraction ( $>80\%$ ) and a lifetime of  $\lesssim 6$  Myr. However, our results for both RCW 57 and 30 Doradus (Paper I) suggest a faster evolution of circumstellar disks around high mass stars, since the disk fractions appear to be slightly lower. This could be caused by photoevaporation of the disks due to the intense radiation environment generated by high mass stars.

*Acknowledgements.* This work could not have been conducted without the great help received from many colleagues within the US CARA and the Australian JACARA organisations whose efforts made the SPIREX/Abu project at the South Pole such a success, to whom we are extremely grateful. We also acknowledge the funding support from the Australian Research Council and the Australian Major National Research Facilities program that made this work possible in the first place. This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This research has made use of the NASA/ IPAC Infrared Science Archive, which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

**Table 7.** (The complete table (251 rows) is only available in electronic form at the CDS). Magnitudes for all sources (including foreground sources and sources below the 90% completeness limit) in RCW 57. Stars with measurements in all four bands are listed first. Then stars with measurements in  $K_s$  and L only, and finally stars just detected in L-band. Column 1 gives the source id. Columns 2 and 3 the RA and Dec respectively in J2000. The coordinates for sources found in all four bands are from the 2MASS point source catalogue (PSC), positions for the remaining stars are determined by reference to 2MASS images. Columns 4, 6, 8 and 10 give the JHK<sub>s</sub>- and L-band magnitudes respectively. Columns 5, 7, 9 and 11 give the photometric errors. For sources detected in all bands, the JHK<sub>s</sub> magnitudes and errors are taken from the 2MASS PSC. A ‘null’ as error indicates a 95% confidence upper limit for the 2MASS magnitude in the PSC. The L-band errors are combined from the errors in daophot and the errors due to the zero point correction. Sources only detected in the  $K_s$ - and L-bands have magnitudes determined from this work. For sources not detected at J, H or  $K_s$  the upper limits on these magnitudes are 15.8, 15.1 and 14.3 respectively. Stars with an IR-excess are marked with an ‘e’ in Col. 12 (comments). Likely foreground stars are marked with ‘fg’. Stars that match sources in Persi et al. (1994) are marked with ‘Persi’ together with the id assigned in their paper. Stars that match the MIR sources in Barbosa et al. (2003) are marked with ‘No’ and the id used in their paper.
