## PREFACE

This study was undertaken at the Water Research Laboratory of the University of New South Wales, Manly Vale, N.S.W. for Unisearch Ltd. on behalf of the Launceston City Council, Tasmania.

Tho study, which was conducted by D.N.Fostor, B.E., A.M.I.E. Lecturcr in Civil Enginecring, was commenced on 20th July 1960 and comploted on 26th August, 1960.

The assistance of the Hydro-Eloctric Commission of Tasmania and the Bureau of Metcorology, Hobart, in providing streamflow and rainfall data for the investigation is gratefully acknowledged.

H.R. Vallentine<br>Associate Profcssor of Civil Engincering Officer in Charge of the Water Research Laboratory.

6.3 Streamflow Records ..... 13
6.4 Calculations ..... 13
7.0 Conclusion ..... 14

A procedure based on rainfall records at seven index stations to predict the peak discharge and time of peak for major floods has been developed. The period of warning of overtopping of the levee banks using daily rainfall records is approximately 15 hours and the accuracy of the estimate approximately $\pm 15$ per cent.

An investigation to study methods of mitigating floods at Launceston was completed by the Launceston Flood Protection Authority in September 1959. In the final report on this investigation (Ref.l p.C59) it was recommended that prior to the construction of the protection works that the flood plain be evacuated when a flood discharge of 70,000 cusecs was forecasted in the South Esk River. At the present time, however, there is no systematic method of forecasting accurately the peak discharge at Launceston for major floods, and before this recommendation could be put into effect a quantitative flood warning procedure is required.

Descriptions of various techniques for flood forecasting have been previously documented (Refs. 1 and 2). However, the majority of the standard procedures proposed would require the installation of more instruments and the collection of additional data over a period of several years. As the time interval before completion of the protection works is relatively short, the value of the standard methods of flood forecasting is therefore limited in their application to the local problem at Launceston and this investigation was aimed at devising the best flood forecasting procedurc based on existing data and using existing instruments.

On this basis it was considered that an estimate of the peak discharge at Launceston to within $\pm 20$ per cent might be possible by either of two basic methods:-
(a) By correlating from records of past floods, the flood stage at Launceston with stage readings upstream. This method is known as the index station method and flood stages at selected headwater stations are used as indices of subsequent stages in the main stream.
(b) By estimating the average rainfall depth over the catchment from records at selected index stations and applying this rainfall to the unithydrograph for the South Esk River after appropriate allowances have been made for rainfall losses and groundwater flow.

Both of these methods have been investigated but owing to the lack of data on major flood stages upstream only the second procedure is considered aplicable at the present time.

### 2.0 Index Station Method

This method attempts to correlate upstream gauge readings with flood stages at Launceston.

The catchment of the South Esk River (Fig.4) has an area above Launceston of $3,355 \mathrm{sq}$. miles and can be roughly divided into four main sectors as follows:-
(a) The South Esk River (not including major tributaries) with a catchment area of 1,304 sq. miles draining the Eastern zone.
(b) The Meander River, a tributary of the South Esk, draining the N.W. area of 589 sq . miles.
(c) The Lake River (not including the Macquarie) a tributary of the South Esk draining 444 sq. miles in the S.W. sector.
(d) The Macquarie River, a tributary of the Lake River, having a catchment area of $1,018 \mathrm{sq}$. miles draining the S.E. portion.

A typical correlation between flood stages at index stations on the headwaters of these catchments and flood stage at Launceston would take the form -

$$
\begin{aligned}
M & =C_{1} m_{1}+C_{2} m_{2}+C_{3} m_{3}+C_{4} m_{4} \\
\text { where } M & =\text { flood stage at Launceston } \\
m_{1} \text { to } m_{4} & =\begin{array}{l}
\text { flood stage at index stations on the headwaters } \\
\text { of each of the major tributaries }
\end{array} \\
C_{1} \text { to } C_{4} & =\begin{array}{l}
\text { constants determined by trial and error from } \\
\text { records of past floods }
\end{array}
\end{aligned}
$$

There was insufficient flood stage data at suitable stations on these rivers, which extended over a sufficient period of time to enable this method to be used for major floods.

An attempt, however, was made to corrclate flood levels at Llewellyn on the South Esk River with flood discharge at Launceston (Figure 1). Although a trend was evident, the plotted points showed a large degree of scatter, due probably to the non-uniform areal distribution of rainfall in the various storms considered.

For these reasons no further investigation of the index station method was undertaken.
3.0 Prediction of Peak Discharges from Rainfall Records

### 3.1 General

A flood forecasting procedure based on forccasting peak discharges at Launceston from rainfall records would include estimates of the following:-
(i) The gross rainfall depth on the catchment.
(ii) The rainfall losses, to obtain the rainfall excess. This involves an estimate of:-
(a) The initial loss to rainfall at the start of the storm as required to satisfy interception and depression storage.
(b) The average loss rate after initial loss has been completed.
(iii) Snowmelt during the storm.
(iv) The temporal variation of the precipitation during the storm.

Once the above data are known the rainfall excess can be applied to the unithydrograph for the catchment to obtain the flood hydrograph at Launceston.

### 3.2 Estimation of Gross Rainfall Depth

Because of the pronounced orographic effects on the areal distribution of rainfall over the South Esk catchment, the most accurate method of estimating the rainfall depth for a storm would be by drawing an isohyetal map and averaging the rainfall according to the areas between the isohyets (Ref. 3 p.78). For practical reasons this method is unsuitable as it would require a much more extensive network of tolegraphic rainfall stations than is at present available as well as increasing the number of man hours required to estimate the rainfall depths.

For this reason, an attempt was made to estimate tho average rainfall dopth by applying weighting factors to the rainfalls recorded at selected index stations according to the Thicssen method (Ref. 3, p.78).

Rainfall depths during six storms were obtained for seven, eleven and fourteen station averages and compared with the more accurate rainfall depth obtained from isohyctal averages of the storms. The stations selected for this analysis and their weighting factors are shown in Appendix "A" and the results of the study have bon summarized in Table I. Only stations which at present report daily rainfall records to the Hobart Weather Bureau by telegraph were used in the analysis in order to avoid the installation of any now instruments.

TABLE I
Average Rainfall Depths by the Thiessen Method as compared with the Actual Rainfall Depth.

| Storm | ActualRainfallDepthfromIsohyetalMap | 7 Station Average |  | 11 Station Average |  | $\begin{gathered} 14 \begin{array}{c} \text { Station Av- } \\ \text { orage } \end{array} \end{gathered}$ |  |

|  |  | $\begin{aligned} & \text { Rainfall } \\ & \text { Depth } \end{aligned}$ | Correction Factor | Rainfall <br> Depth | Correction Factor | $\begin{aligned} & \text { Fainfall } \\ & \text { Depth } \end{aligned}$ | Correction Fact or |
| April 29 | 6.10 | 7.16 | 0.85 | 6.48 | 0.94 | 6.99 | 0.87 |
| Sept. 52 | 2.39 | 2.31 | 1.03 | 2.18 | 1.10 | 2.33 | 1.02 |
| 2-3 May 56 | 2.42 | 2.17 | 1.11 | 1.93 | 1.25 | 2.01 | 1.2 |
| 22-23 May 56 | 1.96 | 2.57 | 0.76 | 1.85 | 1.06 | 1.85 | 1.06 |
| 22-26 May 58 | 2.34 | 2.28 | 1.03 | 2.11 | 1.11 | 2.22 | 1.05 |
| Aug. 58 | 1.62 | 2.44 | 0.66 | 1.62 | 0.92 | 1.88 | 1.16 |

These results indicatc that an cstimate of rainfall depth to within about 20 per cent could be obtained by eithor an eleven or fourteen station average. This was considered satisfactory. It was therefore decided to adopt the eleven station average for estimating the depth of precipitation over the catchment.

It was subsequently found, however, that when the rainfall as obtained by the eleven station average was applied to the unitgraph flood peaks were over estimated for uniform areally distributcd storms. It was considered that this was due to the nature of the topography of the catchment. It was felt that the majority of the flood runoff was produced from the surrounding mountain ranges, with negligible contribution to streamflow from rainfall on the Midand plains. To allow for non-uniformity in the areal pattern of the rainfall it was thereforc decided to modify the eleven station rainfall average by neglecting the rainfall at each of the four stations on the plains. Following this modification it was then necessary to make some slight alterations to the weighting factors of the remaining seven index stations in order to ensure that the true volume of runoff was obtained. Although this meant that the true average gross rainfall depth over the catchment was not calculated the forecasted flood peaks showed closer agreement with the actual peak discharge.

The final index stations and weighting factors adopted were:-

| Station | Weighting Factor |
| :--- | :---: |
| Avoca | 0.135 |
| Lake Leake | 0.103 |
| Mathinna | 0.107 |
| Meander | 0.126 |
| Shannon | 0.083 |
| S\&. Marys | 0.059 |
| Upper Blessington | 0.059 |

3.31 Initial Loss. During the initial period of a storm the majority of the procipitation is used to satisfy the interception and depression storage. It is not until after this initial period that any substantial surface runoff will occur. The volume of rain that falls during this period is termed "initial loss" and may be defined at the quantity of rain that occurs without producing significant run-off.

One method of obtaining an estimate of initial loss is to determine the average rainfall over the catchment for two types of storms - those which produce no significant surface runoff and those which result in only small amounts of surface runoff. Initial loss would thon lie somowhere between the two. If some index of catchment saturation could be determined a plot of the curve separating these two types of storms against the catchment wetness index would give an estimate of initial loss. Seven storms have boen studied and the results have been plotted in Figure 2 using groundwater flow at the start of rise as an index of catchmont wetness.
3.32 Loss Rates. Loss rates from five storms were obtained during the hydrologic studies for the investigation of methods of mitigating floods in Launcoston (Ref. I p. Cl7). These varicd from $2.4 \mathrm{pts} / \mathrm{hr}$ to $9.5 \mathrm{pts} / \mathrm{hr}$. Further research has indicated, however, that this variation was mainly duc to the different mothods used in assessing initial loss. Provided the mothod discussed in Section 3.21 above is used throughout, it was found that a constant loss rate of $2.5 \mathrm{pts} / \mathrm{hr}$ could be used for flood forcoasting without introducing significant crrors. This value was therefore adopted.

### 3.4 Estimation of Snowmelt

Although snow falls in some of the higher elovations of the catchment, the area affected is small and the depth and duration of snow is negligible.

### 3.5 Estimation of Tomporal Pattern of Precipitation

For all the major storms analysed for this investigation it was found that:-
(i) the duration of storm runoff was approximatoly constant on all parts of the catchment,
(ii) the mass curves of rainfall at all pluviometers were aproximately the same when plotted as percentage of total storm rainfall at that station against time aftor the start of rain.

For these reasons the temporal variation of rainfall can be obtained from any available pluviograph on or adjacent to the catchment. In this investigation the records of the pluviograph at Launceston have been used as it was assumed that the headquarters for the calculation of the flood forecast would be best situated in this city.

### 3.6 Derivation of Unithydrographs

Five 6-hour unit hydrograph were derived for the South Esk catchmont during the course of the hydrologic studies for the investigation of flood mitigation measures for Launceston (Ref. I p.C19). It was considered that these were also satisfactory for this study and no further work was carried out on this phase of the investigation.

Further research has indicated, however, that the unit period of the unit hydrograph could be substantially increased without introducing significant errors. In other words either a 12-hour or a 24 -hour unitgraph could be used with a consequent saving in the time required to forecast the flood peak.

As the daily rainfall stations record every 24 hours it could be argued that a 24 hour period would be the best to adopt. In some cases, however, this period would be so much greater than the actual duration of the rainfall that a significant error may arise. For this reason, a l2-hour unitgraph was adopted.

It should also be noted that if the index rainfall stations reported rainfalls every 12 hours (at say 0900 and 2100 hrs .) instead of daily as at present, an additional period of 12 hours warning could be obtained in some cases by using a 12 hour unitgraph.

The average 12 hour unitgraph as derived from the average 6 hour unitgraph given in Ref.1 is shown in Figure 3.

## 3. 7 Derivation of Flood Hydrograph

To predict a flood from a design storm by the use of the unitgraph the first stop is to deduct appropriate loss rates and initial loss from the gross rainfall pattern. The remainder is the excess rainfall hyetograph and is presented with periods corresponding to the unit period of the unitgraph. The surface runoff hydrograph can then be computed from the unitgraph and the excess rainfall hydrograph using the series of equations shown below. In these equations $P_{n}$ is the excess rainfall in inches during the nth period and $X_{n}$ and $Y_{n}$ are the unitgraph and hydrograph ordinates in cusec at the end of the $n_{n}^{n}$ th period after the start of rain.

$$
\begin{aligned}
& P_{1} X_{1}=Y_{i} \quad \ldots-(P) \\
& P_{1} X_{2}+P_{2} X_{1}=Y_{2} \quad \cdots-(2) \\
& P_{1} X_{n}+P_{2} X_{n-1}+\ldots=Y_{n} \quad \cdots-\cdots(n) \\
& P_{r} X_{a}=Y_{b} \quad \ldots-(a+(r-1)) \\
& \text { where } r=\text { No. of rainfall poriods } \\
& a=\text { No. of unitgraph periods } \\
& \mathrm{b}=\text { No. of hydrograph poriods } \\
& =a+(r-1)
\end{aligned}
$$

Fo obtain the total peak flood discharge, base flow must be added to the surface runoff hydrograph. Insufficient data are at prosent available to determine accurately what this incroase should be. For major floods, howevor, the orror introduced by an incorrect assessment of basc flow is small and a suggested allowance is tabulated in Table 5 below. This table may warrant alteration at a later date in the light of additional exporience.

### 4.0 Surmary of Final Flood Forcasting Procodure

### 4.1 General

The proposed procedure for flood forecasting can best be sumnarised by roference to the example given in Appendix "B" to predict the peak discharge of the April 1929 flood.

### 4.2 Sten 1-Gross Rainfall

The average gross rainfall over each 24 hour poriod after the start of rain is obtaincd by multiplying the daily rainfall records at the soven index stations by the woighting factors given in Scction 4.1 and summing as shown in Table 3 of Appondix "B". Thus for the period ending 0900 hours on the 2nd April, 49 points werc recorded at Avoca, 18 points at Lake Loake and so on. Multiplying those figures by the woighting factors of 0.135 for Avoca, 0.103 for Lake Leake ctc. wo obtain the weighted rainfalls of 6.6 points at Avoca, 1.9 points at Lake Leake ctc.

By sumning this column, the average rainfall dopth over the catchment during the first day is calculated at 26.7 points. Similarly the avorage depth of procipitation for the 24 hour poriods onding 0900 hours on $3.4 .29 ; 4.4 .29 ; 5.4 .29$ and 6.4 .29 are $9.8 ; 196.4 ; 412$ and 46.4 points respectively.

### 4.3 Stop 2 - Initial Loss

Initial loss is obtained directly from Figure 2 provided the discharge in the South Esk River at Launcoston prior to the start of rain is known. In April 1929 discharge at Launcoston on the lst April was 437 cusecs. From Figure 2 the initial loss corresponding to this flow is 110 points.

This means that the initial loss was satisfied by the light rain which fcll on the lst and 2nd (rccorded at 0900 hrs 。 on 2nd and 3rd) plus 73 points of the total rain which fell on the 3 rd.

The qucry arises as to what degree light rain prior to the start of the main storm gocs towards satisfying initial loss. The author has found that for the floods analysed, best results wore obtained by considering the rainfall for the three days only prior to the start of excess rainfall. It is felt that rainfall carlice than this will bo reflected in the groundwater flow and will therefore be catored for in Figure 2. Very light rain precoding the main storm, howevor, should be discounted as evaporation would make its effect on initial loss ncgligible.

### 4.4 Step 3-Excess Rainfall Hyetograph

As discussed in Section 3.4 the mass curve of rainfall at any pluviograph on the catchment is approximately constant when plotted as cumulative porcontage of total rain against time. Thus the avorage mass curve of gross rainfall for the ontire catchment can be obtained by multiplying the mass curve as recorded at the Launcoston pluviograph by the ratio of avorage rainfall on the catchmont over a given period to the rainfall at $L_{\text {ranceston }}$ for the same neriod.

If the assumption of a constant temporal pattern of rainfall over the entire catchment was strictly correct then this multiplication factor would be a constant irrespective of the time period chosen. In practice, howevor, its value will depend on the time intorval selected and must be allowed for in the computations.

The method is illustrated in Tahle 4 of Appendix "B". As all the rainfall which fell during the 48 hours ending 0900 hrs . on the 3.4 .29 is used to satisfy initial loss, computation of the mass curvo need only be calculated after this time. The mass curve of gross rainfall as recorded at the pluviograph at Launceston is shown in columns 1 to 3; rain commencing at 1800 hrs , on the 3rd.

Multiplication factors as calculated for each of the time intervals beginning at the start of rainfall and ending at 0900 hours on the 4th, 5 th and 6th April respectively are tabulated on page (i) of Appendix "B". Their values coriespond to 2.36 for the 15 hour period onding 0900 hrs . on the $4 \mathrm{th}, 2.46$ for the 39 hr . period ending 0900 hrs . on the 5 th and 2.06 for the 64 hr . period ending 0900 hrs . on the 6 th . To obtain the cumulated gross rainfall over the catchment at the corresponding times, the cumulated gross rainfall at Launceston is multiplied directly by these factors, as shown in Columns 3 to 5 of Table 4 at 0800 hrs . on the 4 th, 5 th and 6 th respectively. Intermediate values are determined by proportioning the multiplication factors equally between the values obtained above on the assumption of a linear variation as shown in Column 4. Tho computed cumulated gross rainfall over the catchmont is tabulated in Column 5.

To obtain the mass curve of excess rainfall, the initial loss as previously detormined and thereaftor a constant loss rate of $2.5 \mathrm{pts} / \mathrm{hr}$ (or the rainfall rate whichevor is the lesser) is deducted from the gross rainfall mass curve. The cumulated loss is shown in Column 6. The balance of the initial loss of 73 pts . is satisfied somewhere between 2400 hrs . on the 3 rd and 0200 hrs . on the 4 th and is recorded against the reading at 2400 hrs . The cumulated loss is then obtained by adding the 5 points loss which occurs in each of the two hour periods giving a cumulated loss of 78 pts . at 0200 hrs . on the $4 \mathrm{th}, 82 \mathrm{pts}$. at 0400 hrs . on the 5th etc. By doducting the cumulated loss (Column 6) from the curnulated gross rainfall (Column 5) the mass curve of oxcess rainfall is obtained as tabulated in Column (7).

From the excess rainfall mass curve the quantity of rainfall excess which fell in each 12 hour period can be detormined directly as shown in Column 8. The first 12 hour period ends at 1200 hrs . on the 4 th, the rainfall excess being 134 pts . The second 12 hour period onds at 2400 hrs . on the 4 th, the cumulated rainfall excess then being 280 pts . of which 134 pts. fell in the first 12 hour period. The rainfall excess in the second reriod is thereforo 146 pts . and so on for the other periods.

Note 1. In this example a time interval of 2 hours is used to define the mass curve. It is considered that this period will be adequate for all storms which produce major floods at Launcoston.

Note 2. When the duration of the last jocriod of cxcess rainfall is not exactly equal to 12 hours it should be allowed for according to the following rules. If the time interval is 6 hours or more it can be considered as a 12 hour period without any adjustment. If the period is five hours or less the rainfall should be added to that of the preceding 12 hour period.

In the above example the 4 pts . fell in the last period of 2 hours and would therefore be added to the 195 pts. which fell in the preceding 12 hours making the total excess rain which fell in this poriod equal to 199 pts .

Note 3. Where the rainfall rate over a 2 hour period is less than the loss rate of $2.5 \mathrm{pts} / \mathrm{hr} .$, the total rainfall during this period should only be considered as loss since the losses can never exceed rainfall.

### 4.5 Stop 4 - Prodiction of the Surface Runoff Hydrograph

Once the 12 hour excess rainfall hyctograph is known the surface runoff hydrograph can be calculated by the method described in Suction 4.0.

Sample computations for the flood of April 1929 are show in Table 5 of Appondix "B". Ordinates of the 12 hour unitgraph at 6 hour time intorvals are shown in Column (2) whilst the excess rainfall for each 12 hour period aftor the start of excess rain is shown along the first row.

The surface runoff produced by cach poriod of rainfall excess is obtained by multiplying the unitgraph ordinates by the rainfall excess in that particular period as shown in Columns 3, 4 and 6. The total surface runoff is then computed by summing these values with the start of runoff delayod by intervals of 12 hours. Thus the total surface runoff after 24 hours of excess rainfall is calculated by the addition of Columns (3) and (4) as tabulated in Column (5) and after 36 hours by the addition of Columns (5) and (6) as shown in Column (7).

Note. Sufficient calculations noed only be made to assess the time and value of the peak discharge.

### 4.6 Step 5 - Prodiction of Total Poak Discharge

Table 5 shows the magnitude of the peak surfacc runoff. In this example its valuc corresponds to 150,400 cusecs. In order to obtain the total peak discharge base flow must be added according to Table 2 in Section 4.0. From this table base flow will increasc a surface runoff peak of 150,400 cusecs by 12,000 cusecs. Thus the total predicted peak is 162,400 cusecs.

It will be noted that in step 5 of this oxample a proliminary peak discharge of 100,600 cusecs was forecasted at 1000 hrs . on the 5.4.29 before the completion of all rainfall excess. This would enable evacuation of the flood plain to take place 24 hours before the final forceast was made.

## 4. 7 Step 6. Allowance for Storms with non-uniform Temporal Patterns of Rain

The peak discharges of six past floods for which rocords are available were predicted according to the above procedure. The rosults are summarized in Table 8 below.

## Table 8

Estimated Flood Peaks for Past Floods
Date
Forecasted Peak
Actual Peak
Remarks
cfs

13th Oct. 58
18th Aug. 58
26th May, 56
5th May, 56
21st Sept. 52
6th April, 29

53,000
50,000
37,000
31,000
21,000
162,400

48,000
43,000
49,000 Uneven temporal pattern
31,000
33,000
150,000

It will be noted that with the exception of the floods of 26th May 1956 and 21 st September 1952 the forecasted peak flood discharge is within 15 per cent and generally within 10 per cont of the true peak. For these two floods the temporal patterns of rainfall were extremely uneven, there being at least one or more 12 hour periods during the total storm duration when the rainfall rate did not exceed losses.

To allow for storms in which the temporal pattern is extromely uneven, it would appear that the forecasted peak should be increased. To fix accurately the porcentage increase, analyses of a much larger number of storms of this type would be required. Data on such storms are at present not available and it is suggested that until this can be carried out that percentage increascs based on the above estimates be applied according to the following rule.
"Where the excess rainfall in any period of 12 hours during the total storm duration is equal to zero then the forecasted peak discharge shouid be increased by one third".

This rulc applied to the floods of 26th May 1956 and 21st September 1952 would increase the forecasted peaks to 49,000 and 28,000 cusecs respectively as compared with the actual peak flows of 49,000 and 33,000 respectively.

### 4.8 Step 7 - Final Forccast

The magnitude of the peak flood discharge is calculated in Step 5 or Step 6 according to the type of storm being analysed.

From Table 4, showing the mass curve of rainfall excess, and Table 5, showing the surface runoff hydrograph, the time when excess rainfall commenced and the time to peak after the start of rainfall oxcess can be determined respectively. This data enablos the time of arrival of the flood crest to ke calculatod as shown in Appendix "B".

Preliminary forecasts prior to the completion of rain can be obtained in the same manner if so desired. For example for the flood of April 1929 as tabulated in Appendix "B" a peak of at least 100,600 cusecs occurring at 0600 hrs . on 6.4 .29 is predicted 24 hours before the final forecast of 162,400 cusces occurring at 1800 hrs . on 6.4.29 is made.

Similarly the time when the levec banks will be overtopped can also be estimated. The average discharge at which the levee banks are overtoped is ostimated at 90,000 cusecs (Ref.1 p.C59). For the April 1929 flood it is seen from Table 5 that this flow discharge less the allowance of 8,000 cusecs for base flow, occurred 40 hours after the start of rainfall excess at 2400 hrs . on 3.4 .29 . Thus the time when the levee hanks are ovortoped is estimatcd at 1600 hrs . on 5.4 .29 . The actual time when the levec banks wore overtopped was Oi30 hrs. on 6.4 .29 or $5 \frac{1}{2} \mathrm{hrs}$. lator than that forccastod.

### 5.0 Rcsults of Forccasting Proccdurc Applicd to Past Floods

The procedure developed above has boen applicd to six past floods for which rocords aro available. The results are summarised in Table 9 below:-

Table 9
Estimates of Flood Poaks and Time of Poak for Past Floods

| Date of Storm | Time of Forceast | Forecasted Peak cusecs | Actual Poak cusecs | Forcasted <br> Time of Pcak | Actual <br> Timc of Peak |

| April 29 | 2) 1000 hrs . on 6 th | 162,400 |  | 1800 hrs . on 7th |  |

### 6.1 Daily Rainfall Records

Daily rainfall records as read at 0900 hrs . should be telegraphed to the flood warning centre as carly as possible after $0900 \mathrm{hrs}$.

The index rainfall stations selected for the scheme are shown below with suggested altornative stations shown in brackets in the case of an emergency breakdown in the reports on rainfall during a flood.

```
Avoca (Lewis Hill, Fingal)
Lake Lloake (Lewis Hill)
Mathinna (Tower Hill)
Meander (Golden Valley, Caveside, Mole Creek)
Shannon (Breona, Steppes, Arthur Lakes, Intorlaken)
St. Marys (German Town, Cullenswood)
Upper Blessington (Ringarooma)
```

These station alternatives are only intended for use in the case when telegraphic contact to any of the main index stations is broken.

Each of the main index stations selected are at present telegraphic stations for the Hobart Weather Bureau although in some cases no reports are given on Sundays.

### 6.2 Pluviograph Records

Pluviograph records aro required from any arbitrary station on or adjacent to the catchment. In the procedure described above, records from Launceston are used although this is not essential. In the case of a breakdown in operation of the pluviograph at Launceston, additional instruments are located at Westorn Junction Aerodrome and Scottsdale which would be satisfactory.

### 6.3 Streamflow Records

Discharge in the South Esk River at Launceston prior to the start of rain is required to estimatc initial loss. This will nocessitate daily records of flow either by the H.E.C. at Trevallyn Dam or by a separate obscrver at the H.E.C. gauging station at Hadspen.

### 6.4 Calculations

All calculations can be carriod out to sufficiont accuracy by slide rule. A suggested form of tabulation is shown in Appendix "B".

Insufficiont data are available to onable stage forecasting of major floods at Launcoston to be uscd with any degreo of confidence. Howevor, a procedure for forccasting peak flood discharges from rainfall records has been developed which has given an accuracy of 15 por cont or better in the forecasted peak discharge for six past floods and can therofore be expectod to work satisfactorily for future storms.

For the flood of April 1929 a forccast that the levec banks would be ovortonied was made $15 \frac{1}{2}$ hours preceding their failure while the peak discharge was predicted 14 hours bofore its occurrence. This period of warning could be increased if rainfalls at the index stations were reported cvery 12 hours instead of daily as at present.
